Abstract

The statistical analysis of data that are well represented by networks, or graphs, is a rapidly developing field. In particular, many aspects of the world, including economics, telecommunications, social websites, and transportation grids, to name a few, are well characterized by graphs. While much work has been devoted to studying the statistics of individual graphs, less attention has been given to the analysis of populations of graphs. Our interest here is to develop classifiers that operate directly on graphs, without requiring embedding the graphs into vector spaces, or extracting features. Therefore, our approach is to develop a joint model, $\mathbb{P}[G, Y]$, characterizing the distribution of random graphs, G and classes, Y. We study some simple special cases by assuming edges are conditionally independent, yielding stochastic block models. We develop a few classifiers, and prove that they are consistent. Moreover, we prove that performance depends on the model, the size of the graph, and the number of samples. In our motivating example, the graphs correspond to brain connectivity, i.e. connectomes, of individuals. These results suggest several avenues for the development of classification algorithms for graphs.

1 Introduction

Current technology facilitates acquiring large swaths of data in myriad diverse fields, ranging from telecommunications to neuroinformatics. As data *collection* technologies become increasingly sophisticated, they beckon an analogous development of data *analysis* technologies. Statistical theory, and in particular, pattern recognition, has therefore received widespread attention and devotion in the recent decades, including an explosion in so-called "machine learning" techniques, including both supervised and unsupervised learning. Supervised learning algorithms have largely focused on problems that loosely satisfy the following assumptions: data has been exchangeably from some model: $(x_s, y_s) \overset{exch.}{\sim} \mathbb{P}[X, Y]$, where each $x_s \in \mathcal{X} \subseteq \mathbb{R}^p$ is a "feature vector," $y_s \in \mathcal{Y} \subseteq \mathbb{R}^q$ is a (set of) class variable(s), and $\mathbb{P}[X, Y]$ is some joint distribution [1]. Given these assumptions, one then desires to build a function that utilizes training data to make a prediction of y given a new x, $f : \mathcal{X} \times (\mathcal{X} \times \mathcal{Y})^S \mapsto \mathcal{Y}$, where S is the number of training exemplars.

Here we are interested in a slightly different setting. In particular, rather than assuming that features collectively form a vector, we assume that the features form a graph, where a graph is characterized by an $n \times n$ element adjacency matrix indicating the connectivity between vertices. The space of graphs, $\mathcal{G}$, is not in $\mathbb{R}^p$, and therefore, most supervised learning algorithms can not be naïvely applied directly to problems of this form. Importantly, many arising and existing data sets are more naturally represented as graphs than vectors, including telecommunications grids, social networks, the internet, and brains. Thus, tools designed specifically to operate on graph spaces would potentially facilitate extracting more information from these data.

To date, most work on these kinds of problems has utilized "graph kernels" [2]. More specifically, the investigator first defines a set of graph kernels, projects each graph into the graph kernel space, and then utilizes standard machine learning techniques [3], typically some kind of boosting algorithm [4] (for example, [5, 6, 7]). [8] and [9] defined various embeddings and then built classifiers based on distance between embedded graphs). [10] and [11] assume edges are independent, and then use standard tools to perform classification.

A somewhat different approach is considered here, based on the statistical theory of pattern recognition [1]. Specifically, data is assumed to be sampled exchangeably from some joint distribution, $\mathbb{P}[G, Y]$, where G is a random-*graph*, not a random-*vector*. Given this assumption, one can build a classifier that takes as input training data (in the form of graphs and their classes) and a new graph, g, and predicts the most likely class y. Of primary interest here is the

development of consistent classifiers, that is, classifiers guaranteed to converge to the Bayes optimal classifier with enough data. Moreover, the preference is that these classifiers converge quickly, as data is often limited. Therefore, one can describe a number of models, each with distinct assumptions. For each model, a classifier is designed specifically to be consistent for that model, and to converge quickly to Bayes optimal performance. Simulations confirm that the classifiers behave as they should. These classifiers are then applied to "connectome" data, where each graph corresponds to the macroanatomical structure of a human brain. These classifiers can differentiate gender with better accuracy then other previously proposed approaches, in less time, with more interpretability.

2 Methods

2.1 Background

2.1.1 Notation

Both vectors and matrices will be indicated by bold notation, $\boldsymbol{x}$. The real number line will be $\mathbb{R}$, the dimensionality of $\boldsymbol{x}$ will be indicated by d, e.g., $x \in \mathcal{X} \subseteq \mathbb{R}^d$, where $\subseteq$ indicates a subset (possibly equal), where script upper case latin letters denote sets, with cardinality indicated by $|\mathcal{X}|$.

Upper case latin letters are random objects, $X : \Omega \mapsto \mathcal{X}$, mapping from the universal sample space Ω to the sample space, $\mathcal{X}$. A sample will be indicated by lower case latin letters, e.g., $x \in \mathcal{X}$. The probability distribution of X will be $\mathbb{P}[X]$, and the probability mass function of X taking value x will be written $\mathbb{P}[X = x]$, or just the notationally abusive shorthand, $\mathbb{P}[x]$.

A random graph, G, takes values $g \in \mathcal{G}$, defined by a set of n vertices $\mathcal{V} = \{V_i\} = \{V_1, \ldots, V_n\}$ and edges (or arcs) between them. The value of each edge, a_{ij}, is encoded in a $n \times n$ element array called an adjacency matrix, $\boldsymbol{a} = \{a_{ij}\}$. When the set of vertices is fixed, the graph is called a *labeled graph*. When comparing multiple graphs, if they are all labeled graphs, then all of the information about the graph is within the adjacency matrix, so one can simply refer to the random adjacency matrix $\boldsymbol{A}$. Below, we assume all edges are binary, thus $a_{ij} \in \{0, 1\}$. A hollow graph forbids self-loops, so $a_{ii} = 0 \quad \forall i \in [n]$. Undirected graphs require that $a_{ij} = a_{ji} \quad \forall i, j \in [n]$ (note that $a_{ij} = 1$ indicates the presence of an edge from V_j to V_i). Directed graphs impose no such requirements. The number of possible labeled graphs for a set of vertices is $|\mathcal{G}| = 2^d$, where d is the dimensionality of the graphs (and this is also the number of distinct adjacency matrices). A *simple graph* has a hollow, symmetric, and binary adjacency matrix, so $d = \binom{n}{2}$. Directed graphs with self-loops have $d = n^2$. We denote the probability distribution of a random graph, $\mathbb{P}[G]$. Below, we elaborate on various probability distributions on graphs.

Let Y be a random class, taking values $y \in \mathcal{Y}$. We are particularly interested in scenarios in which $\mathcal{Y} = \{0, 1\}$, in which case y is called a class.

Given these definitions, a joint distribution, $\mathbb{P}[G, Y]$, specifies the probability of observing any graph $g \in \mathcal{G}$ (to be defined below) and any class $y \in \mathcal{Y}$. The model is the collection of all possible joint distributions under consideration, $\mathcal{P} = \{\mathbb{P}[G, Y]\}$.

Let $\mathbb{P}[g|y]$ indicate the *likelihood* of observing g given y, $\mathbb{P}[y]$ denote the *prior* probability of observing y, and $\mathbb{P}[y|g]$ be the *posterior* probability of observing y given g. T

A model is said to be parametric if the distribution can be characterized entirely by a finite set of parameters, $\boldsymbol{\theta} \in \boldsymbol{\Theta} \subseteq \mathbb{R}^p$, where $p < \infty$ is the dimensionality of the parameter. Strictly speaking, the parameter of the model must be *identifiable*. Formally, $\boldsymbol{\theta} : \boldsymbol{\Theta} \mapsto \mathcal{P}$ is the inverse map from $\boldsymbol{\Theta}$ to $\mathcal{P}$ if and only if the latter map is one-to-one, that is $\mathbb{P}_{\boldsymbol{\theta}_1} = \mathbb{P}_{\boldsymbol{\theta}_2} \Rightarrow \boldsymbol{\theta}_1 = \boldsymbol{\theta}_2$ (and $\mathbb{P}_{\boldsymbol{\theta}_i}$ indicates a distribution characterized by $\boldsymbol{\theta}_i$).

Throughout, data is assumed to be sampled exchangeably from some true (but typically unknown) distribution, $x \overset{exch.}{\sim} \mathbb{P}_{\boldsymbol{\theta}}[G, Y]$. A collection of S data samples is denoted by $\mathcal{D}_S = \{(G_s, Y_s)\}$.

A parameter estimate uses some data to obtain an estimate of the true (but typically known) parameter $\boldsymbol{\theta}^*$, $\hat{\boldsymbol{\theta}}_S : \mathcal{X}^S \mapsto \boldsymbol{\Theta}$. An unbiased estimator is one for which its expectation equals the true parameter value: $\mathbb{E}[\hat{\boldsymbol{\theta}}_S] = \boldsymbol{\theta}^*$. An asymptotically unbiased estimator is one for which $\mathbb{E}[\hat{\boldsymbol{\theta}}_S] \to \boldsymbol{\theta}^*$ as $S \to \infty$. Technically, this is a *sequence* of estimators, as each estimator is a function of S data points, so they have different domain spaces, and are therefore different functions. A consistent estimator (sometimes called an asymptotically consistent estimator) is a sequence of estimators that converges in probability to $\boldsymbol{\theta}^*$. Formally, an estimator is consistent if and only if $\lim_{S \to \infty} \mathbb{P}[\hat{\boldsymbol{\theta}}_S = \boldsymbol{\theta}^*] = 1$.

2.1.2 Basic classification theory

In the graph classification setting, we define a graph classifier as any function that takes as input a graph g and outputs an expected class, $f : \mathcal{G} \mapsto \mathcal{Y}$, when $\mathcal{Y}$ is discrete. Graph classification quality is assessed by misclassification rate:

$$L_f = \mathbb{P}[f(G) \neq Y] = \int_{g \in \mathcal{G}} \mathbb{P}[f(g) \neq y]\mathbb{P}[g]dg. \tag{1}$$

We would like to find a graph classifier, f^*, with minimum misclassification rate, also called the Bayes optimal graph classifier. It can be shown that selecting the class that maximizes the class-conditional posterior is Bayes optimal [1]:

$$\hat{y} = f^*(g) = \underset{f \in \mathcal{F}}{\operatorname{argmin}} L_f(g) = \underset{y \in \{0,1\}}{\operatorname{argmax}} \mathbb{P}[y|g] = \underset{y \in \{0,1\}}{\operatorname{argmax}} \mathbb{P}[g|y]\mathbb{P}[y] \tag{2}$$

where $\mathcal{F}$ is the space of all possible classifiers. The misclassification rate, or simply error, of the Bayes optimal graph classifier is called the *Bayes error* (or *Bayes risk*). Because f^* is typical unknown, one can approximate $f^*$by utilizing training data. In particular, we will assume a corpus of S data points have been sampled exchangeably from the joint distribution, $(g, y), \{(g_s, y_s)\} \overset{exch.}{\sim} \mathbb{P}[G, Y]$, for $s \in [S]$, where $[S] = \{1, 2, \ldots, S\}$ and $\mathcal{D}_S = \{(g_s, y_s)\}$ denotes the set of S samples. Then, we can construct an classifier estimate: $\hat{f}(\cdot; \mathcal{D}_S) : \mathcal{G} \times (\mathcal{G} \times \mathcal{Y})^S \mapsto \mathcal{Y}$. A *Bayes plug-in* classifier first estimates the likelihood $\mathbb{P}[G|Y]$ and prior, $\mathbb{P}[Y]$, and then plugs them in to (2) to obtain:

$$\hat{y} = \underset{y \in \{0,1\}}{\operatorname{argmax}} \hat{\mathbb{P}}[g|y]\hat{\mathbb{P}}[y]. \tag{3}$$

Assessing the quality of an estimated classifier is a sticky wicket, as the integral in (1) is typically intractable without an infinite amount of data. Instead, we typically approximate this integral using a (sub-)sampling procedure. In particular, select subsets of the data: $\{\mathcal{D}_{s_1}, \ldots, \mathcal{D}_{S_C}\}$, where each $\mathcal{D}_{S_c} \subseteq \mathcal{D}_S$, and compute the *cross-validated error*, an estimate of the misclassification rate for an estimated classifier:

$$\hat{L}_{\hat{f}(\cdot;\mathcal{D}_S)} = \sum_{c=1}^{C} P[\hat{f}(g; \mathcal{D}_{S_c}) \neq y]P[\mathcal{D}_{S_c}], \tag{4}$$

noting that (4) generalizes the ideas of "leave-one-out" and related approaches by allowing any sampling strategy, any size subsets, and any number of subsamples.

2.1.3 Consistency

Consistent Estimators Each of the above models is characterized by a set of parameters, either p, $\{p, q, \mathcal{M}_{inc}\}$, or $\{p, q, \mathcal{M}_*\}$. The maximum likelihood estimator (MLE) is consistent for a Bernoulli random variable:

$$\hat{p}_S = \frac{1}{S} \sum_{s=1}^{S} a_s \tag{5}$$

Each edge in each model is Bernoulli, so each edge can be estimated independently using Eq. (5). Therefore, the plugin estimator for any independent edge random graph model could be:

$$\hat{\mathbb{P}}[A = a] = \prod_{i,j \in [n]} a_{ij}^{\hat{p}_{ij}} (1 - a_{ij})^{1 - \hat{p}_{ij}} \tag{6}$$

where we have dropped the subscript S for brevity. Note however, that if any $\hat{p}_{ij} = 0$, then $\mathbb{P}[A = a] = 0$. Therefore, we smooth the MLE by using a robust estimator, specifically, an M-estimator. An M-estimator is any estimator that maximizes a certain contrast function:

$$\boldsymbol{\theta}_M = \underset{\boldsymbol{\theta} \in \boldsymbol{\Theta}}{\operatorname{argmin}} \sum_{s=1}^{S} \rho(a_s, \boldsymbol{\theta}) \tag{7}$$

where $\rho(a_s, \boldsymbol{\theta})$ is called a contrast function. For instance, the MLE uses $\rho = -\log \mathbb{P}_{\boldsymbol{\theta}}[a_s]$. Here, we propose a slightly modified contrast function:

$$\hat{p}_M = \frac{\sum_{s=1}^{S} a_s + 1/(2S)}{S + 1/(2S)} \tag{8}$$

so that the parameter estimate is never actually zero. Eq. (8) implicitly defines the following contrast function

$$\rho(a_s, \boldsymbol{\theta}) = -\frac{a_s + 1/(2S)}{S + 1/(2S)}. \tag{9}$$

Note that not only does this M-estimator provide some smoothing properties, akin to regularization, it is also a robust estimator, that is, an estimator robust to various model misspecifications (for instance, edge independence is likely to be inaccurate often). Other estimators with both these properties, smoothing and robustness, include the *maximum a posteriori* estimators, which we do not consider here, other than to acknowledge their existence and potential great utility.

Note that for these simple models, better parameter estimates are readily available. For instance, averaging over $\hat{p}_{ij}$ in the ER model would give an improved estimate for p (bias is not introduced, and variance is reduced, so the estimate is better from a bias-variance trade-off perspective). However, we abstain for such averaging so that the theory and simulations generalize to more heterogeneous models (where each a_{ij} might be distributed according to its own p_{ij}).

Consistent classifiers For each of the above three models, we desire to have estimators that are consistent. Under certain conditions, consistent estimators can be plugged into (2) to obtain consistent classifiers.[1]

The Naïve Bayes graph classifier, which assumes all edges are independent, is given by:

$$\begin{aligned} f(g) &= \underset{y}{\operatorname{argmax}}\, \mathbb{P}[g, y] = \underset{y}{\operatorname{argmax}}\, \mathbb{P}[g|y]\mathbb{P}[y] \\ &= \underset{y}{\operatorname{argmax}} \prod_{i,j \in [n]} \mathbb{P}[a_{ij}|p_{ij}^y]\mathbb{P}[y] \\ &= \underset{y}{\operatorname{argmax}}\, \mathbb{P}[y] \prod_{i,j \in [n]} \text{Bern}(a_{ij}; p_{ij}^y) \\ &= \underset{y}{\operatorname{argmax}}\, \pi^y \prod_{i,j \in [n]} a_{ij}^{p_{ij}^y} (1 - a_{ij})^{1 - p_{ij}^y}, \end{aligned} \tag{10}$$

where $\pi^Y = \mathbb{P}[Y]$, and p_{ij}^Y is the probability of edge (i, j) existing in class Y.

Upon presuming that a signal subgraph exists, one can outperform the naïve Bayes classifier. In particular, if one assumes that edges are independent in both classes, but that only a small subset of edges differ between the two classes, $\mathcal{M} = \{E_{ij} | p_{ij}^0 \neq p_{ij}^1\}$, then one can use this information to obtain a better classifier, by only looking at the signal subgraph:

$$f(g) = \underset{y}{\operatorname{argmax}}\, \pi^y \prod_{(i,j) \in \mathcal{M}} a_{ij}^{p_{ij}^y} (1 - a_{ij})^{1 - p_{ij}^y}. \tag{11}$$

This approach does not depend on homogeneity of edges, each edge a_{ij} could be sampled according to its own potentially unique distribution p_{ij}.

Because the parameters will be unknown, one must first estimate them. Given the estimates, they can be plugged in to either (10) or (11). Estimating p and q is quite trivial given $\mathcal{M}$, which could potentially be the complete graph (in the ER case). Specifically, $\hat{p}$ is the mean of $\hat{p}_{ij}$ for $(i, j) \notin \mathcal{M}$, and $\hat{q}$ is the mean of $\hat{q}_{ij} \in \mathcal{M}$. The more difficult task is estimating $\mathcal{M}$, the signal subgraph. Below, we suggest several possible approaches to finding the signal subgraph.

3 Models

Here, we describe a few different independent edge models, each with different constraints on the parameters.

[1] which conditions?

3.1 Identical and independent edge model

Perhaps the simplest random graph model one could assume is the Erdös-Rényi (ER) random graph, which asserts that each edge is independent and identically distributed (iid): $\mathbb{P}[A_{ij} = p]$, $\forall i, j \in [n]$. To use this assumption for graph classification, we would assume that

$$\begin{aligned}\mathbb{P}_{\boldsymbol{\theta}}[G] = \mathbb{P}_{\boldsymbol{\theta}}[\vec{\boldsymbol{A}}] &= \prod_{i,j\in[n]} \mathbb{P}_{\boldsymbol{\theta}}[A_{ij}] \\ &= \prod_{i,j\in[n]} \text{Bern}(a_{ij}; p) = \prod_{i,j\in[n]} a_{ij}^{p}(1-a_{ij})^{1-p} \end{aligned} \tag{12}$$

where $\boldsymbol{\theta} = p$. The distribution of these ER graphs is therefore determined entirely by n and p (and assumptions of whether the graph is directed and/or hollow). This iid model can be easily generalized by relaxing the second 'i', namely, letting edges by independent, but not identically distributed.

Below, we elaborate on two special cases of this generalization. In each case, some edges are Bern(p), and others are Bern(q), where $q > p$; the two models differ in which edges have probability q. In each case, the *signal subgraph* is the graph defined by the edges with probability q. Figure 1 shows examples of all three models.

3.2 Incoherent model

Above, the distribution of the entire graph is given by n and p, here we allow for certain edges to have probability q. In particular, we consider the set of m edges, $\mathcal{M}_{inc} = \{A_{ij} | (i,j) \in \mathcal{M}_{inc}\}$, where $|\mathcal{M}_{inc}| = m$, each of which has probability q, yielding the following model:

$$\mathbb{P}_{\boldsymbol{\theta}}[G] = \prod_{(i,j)\notin\mathcal{M}_{inc}} \text{Bern}(a_{ij}; p) \prod_{(i,j)\in\mathcal{M}_{inc}} \text{Bern}(a_{ij}; q). \tag{13}$$

The parameters of this model are therefore: $\boldsymbol{\theta}_{inc} = (p, q, \mathcal{M}_{inc})$.

3.3 Star$_1$ model

In the above model, the edges with probability q could be uniformly scattered across all vertices. Here, we assume that all the edges with probability q share a common neighbor. More formally, $\mathcal{M}_* = \{A_{ij} | V_i = V_* \text{ or } V_j = V_*\}$. This leads to a model identical to (13), except replace the $\mathcal{M}_{inc}$ with $\mathcal{M}_*$. The parameters of the Star$_1$ models are therefore: $\boldsymbol{\theta}_* = (p, q, \mathcal{M}_*)$. The Star$_1$ model can easily be extended to a Star$_k$, for any $k < n$.

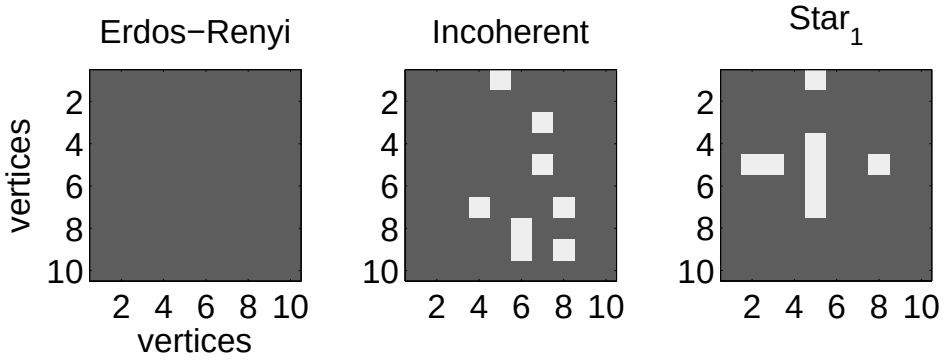

Figure 1: Schematic depicting the probability of each edge for the three models

4 Signal subgraph searches

4.1 Exhaustive search for signal subgraphs

The number of signal subgraphs is equal to the number of graphs in the random graph family, $|\mathcal{G}| = 2^d$, where d is around n^2 depending on assumed constraints (see Section **??** for details). Thus, one could enumerate all possible signal subgraphs, $\{\mathcal{E}_1, \ldots, \mathcal{E}_{2^d}\}$, and compute $\hat{L}_{f_{\mathcal{E}_c}(\cdot;\mathcal{D}_S)}$ for each $c \in [2^d]$. Finally, let $\hat{c} = \text{argmin}_c \hat{L}_{f_{\mathcal{E}_c}(\cdot;\mathcal{D}_S)}$. Unfortunately, even when n is relatively small (e.g., ≈ 10), 2^d is quite large ($\approx 10^{30}$), making this approach computationally intractable. Also, this approach depends on the particular classification algorithm. It is therefore often desirable to be able to search more efficiently for signal subgraphs independent of the classifier.

4.2 Incoherent signal subgraph search

In the face of such a large subspace, many algorithms have been developed to find approximately optimal subspaces, including most prominently so-called forward search and backwards prune strategies [12]. In general, these (greedy) strategies have no guarantees of consistency even though they can be quite computationally intensive.

However, given the independent edge assumption, we can compute the significance of each edge independently, to obtain a rank ordering of edges. More specifically, given p^0_{ij} and p^1_{ij} for all $i, j \in [n]$, one can compute the distance, $\delta_{ij} = d(p^1_{ij}, p^0_{ij})$, which conveys the difference in position between the two classes. δ_{ij} is thus an uncorrected test-statistic. Importantly, for all $(i, j) \in \mathcal{M}$, $d(p^1_{ij}, p^0_{ij}) > 0$, whereas for all $(i, j) \notin \mathcal{M}$, $d(p^1_{ij}, p^0_{ij}) = 0$. Thus, if one had the true δ_{ij}'s, finding the signal subgraph would be trivial. Unfortunately, because p_{ij} is unobserved, δ_{ij} must be estimated.

A naïve estimator for δ_{ij} is simply $\hat{\delta}_{ij} = |\hat{p}^1_{ij} - \hat{p}^1_{ij}|$, where $|\cdot|$ indicates the absolute value. Given these estimates, one could then rank them, $\delta_{(1)} \geq \ldots \geq \delta_{(d)}$. If the number of edges in the true signal subgraph, m, were known, then one could choose the biggest m distances, $\hat{\delta}_{(1)}, \ldots, \hat{\delta}_{(m)}$.

The above defined $d(\cdot, \cdot)$ does not consider the variance of the estimators. In particular, the variance of the estimators $\hat{p}$ is a function of the true p, because it has a binomial distribution: $\hat{p}^y_{ij} \sim$Binomial(s_y, p^y_{ij}). Therefore, it would be desirable to scale the confidence of the difference between the two classes by the uncertainty around each estimate. One option is to normalize each estimate by its variance:

$$\hat{\delta}^c_{ij} = |\frac{\hat{p}^1_{ij}}{\hat{p}^1_{ij}(1 - \hat{p}^1_{ij})} - \frac{\hat{p}^0_{ij}}{\hat{p}^0_{ij}(1 - \hat{p}^0_{ij})}|, \tag{14}$$

which is akin to a z-score when estimators have a Gaussian distribution, which is the most powerful test statistic in that domain (the c superscript indicates *corrected*). Unfortunately, the estimator in Eq. (14) does not appear to have that property for finite samples.

4.2.1 Model selection

When the size of the signal subgraph is known, then the optimal selection of m edges is simply $\delta_{(1)}, \ldots, \delta_{(m)}$, the m edges with the lowest δ's. When m is not known a priori, m must also be estimated, which is a model selection problem. Cross-validation can then be used to choose the optimal m, given the data $\mathcal{D}_S$. More specifically, one obtains a sequence of classifiers, $\hat{f}_1, \ldots, \hat{f}_{m'}$, each one including an additional dimension, and then uses the one with the lowest empirical risk, $\hat{L}_{\hat{f}_{m'}(\cdot;\mathcal{D}_S)}$, that is, let $\hat{m} = \text{argmin}_{m'} \hat{L}_{f_{\hat{\mathcal{E}}_{m'}}(\cdot;\mathcal{D}_S)}$. This approach is hereafter referred to as the *incoherent signal subgraph* search method. Given $\mathcal{E}_{\hat{m}}$, one can apply any of the above classifiers to the selected subgraph. Note that this approach assumes that the class-conditional signal is somewhat *sparse*. Figure 2 depicts δ's for different assumptions on the class conditional differences. The left panel shows an example where class conditional differences are dense, and the middle panel shows an example where these differences are sparse. A third option, depicted on the right, shows the class-conditional difference being both sparse and structured.

4.3 Star$_1$ signal subgraph search

When the signal subgraph is expected to have some structure, we can utilize this prior information to improve our search. Specifically, assume that one of the classes is a Star$_1$ model. In this case, instead of looking for *edges* to define

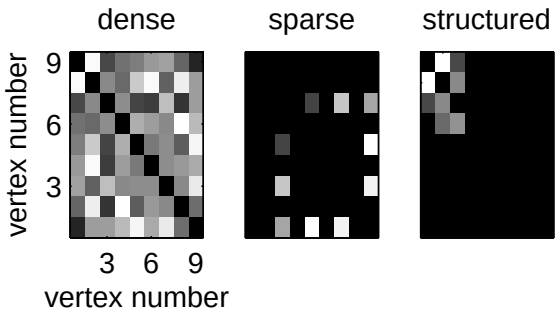

Figure 2: Various kinds of class-conditional differences suggesting different algorithms to estimate the signal subgraph. The left panel shows a dense signal, meaning that no signal subgraph will contain much information. The middle panel shows a sparse signal subgraph, suggesting using the incoherent signal subgraph search method. The right panel shows a structured sparse signal subgraph, suggesting using the coherent signal subgraph search method.

the signal subgraph, one can look for anomalous *vertices*. For simplicity, assume that $q > p$. Now, define the degree of a vertex as the number of edges incident to it, that is, $d_i = \sum_j A_{ij}$. In the Star$_1$ model, the expected degree of V_* is larger than the expected degree of all the other vertices, because $q > p$. Therefore, if the true expected degree of each vertex was available, one could sort them, $d_{(1)}, \ldots, d_{(n)}$, and then the vertex with the largest expected degree would be V_*. In the classification domain, instead of computing the degree of each vertex, one can compute the degree difference for each vertex: $\delta_i = |d_i^0 - d_i^1|$. Then, the vertex with the biggest degree difference is V_*.

Although the true expected degree is unavailable typically, one can easily estimate the degree of each vertex for each class using:

$$\hat{d}_i^y = \frac{1}{s_y} \sum_{s \in \mathcal{S}_y} \sum_{j \in [n]} a_{s;ij} \tag{15}$$

where $\mathcal{S}_y$ is the set of observations in class y, s_y is the cardinality of that set, and $a_{s;ij}$ is edge indicator for sample s. Estimating the degree difference for each vertex, $\hat{\delta}_i = |\hat{d}_i^0 - \hat{d}_i^1|$, and ranking them to find the largest one, $\hat{\delta}_{(1)}$, is therefore an estimator of the signal subgraph.

Note that there is no model selection problem here, as it was assumed that only a single vertex had a different expected degree. When this assumption is not made, a similar strategy can be employed as above to perform model selection for this model.

5 Theoretical results

In this section, we provide a number of theorems and their corresponding proofs, related to classifying independent edge random graph models.

5.1 Estimator consistency

Theorem 1. *If a is Bernoulli distributed with probability p, then $\hat{p}_M$ is a consistent estimator for p, where $\hat{p}_M$ is defined by Eq.* (8)*.*

Proof. To prove that an estimator is consistent, it is sufficient to show that it converges to another estimator known to be consistent.

$$\begin{aligned} \mathbb{E}\left[\frac{\sum_{s\in[S]} a_s + 1/(2S)}{S + 1/(2S)}\right] &= \frac{\mathbb{E}[\sum_{s\in[S]} a_s] + 1/(2S)}{S + 1/(2S)} \\ &= \frac{\mathbb{E}[\sum_{s\in[S]} a_s]}{S + 1/(2S)} + \frac{1/(2S)}{S + 1/(2S)} \end{aligned} \tag{16}$$

As $S \to \infty$, the second term converges to zero, and $S + 1/(2S)$ converges to S, yielding the MLE, which is known to be consistent. □

Theorem 2. *The set $\hat{\delta}_{(1)}, \ldots, \hat{\delta}_{(m)}$ converges to $\mathcal{M}$ as $n \to \infty$.*

Proof. As $n \to \infty$, $\hat{p}^y_{ij} \to p^y_{ij}$ for all $i, j \in [n]$ and $y \in \{0, 1\}$. Thus, $\hat{\delta}_{ij} = |\hat{p}^0_{ij} - \hat{p}^1_{ij}| \to \delta_{ij} = |p^0_{ij} - p^1_{ij}|$. The result therefore follows trivially. □
